## Prime Factorization In log(n) After Sieve

By [riningan](#), 4 years ago, , 

We use Eratosthenes sieve for prime factorization, storing the primes in an array. But for that, we need to find the primes less than or equal to  $\sqrt{n}$  which divide  $n$ . There are about  $n/\log(n)$  primes less than or equal to  $n$ . So, the complexity is roughly  $\sqrt{n}/\log(\sqrt{n}) * \log(n)$ . But if  $n$  is asked to be factorized completely where  $n$  is within the Sieve range, then we can factorize  $n$  in  $\log(n)$  complexity. And the trick is fairly small. Observe, that, we don't need to run a whole  $\sqrt{n}$  loop for finding the prime divisors. Instead, we can even store them when  $n$  is in the range, say  $n \leq 10^7$ . But the tricky part is not to store all the prime divisors of  $n$ . Let's see the following simulation. Take  $n = 60$ . We want to factorize  $n$ . We will store the **smallest prime factors only**. This does the trick. If  $n$  is composite, then it has such a prime factor, otherwise  $n$  is a prime and then the  $n$  itself is the smallest prime factor. It is obvious, for any even number  $n$ ,  $sp(n)=2$ . Therefore, we only need to store these primes for odd  $n$  only. If we denote the smallest prime factor of  $n$  by  $sp(n)$ , for odd  $2 \leq n \leq 30$ , we get the following list.

$sp(2)=2$ ,  $sp(3)=3$ ,  $sp(5)=5$ ,  $sp(7)=7$ ,  $sp(9)=3$ ,  $sp(11)=11$ ,  $sp(13)=13$ ,  $sp(15)=3$ ,  $sp(17)=17$ ,  $sp(19)=19$ ,  $sp(21)=3$ ,  $sp(23)=23$ ,  $sp(25)=5$ ,  $sp(27)=3$ ,  $sp(29)=29$ .

Then the factorization is very simple. The optimization is needed only once, when the Sieve() function runs.

```
bool v[MAX];
int len, sp[MAX];

void Sieve(){
    for (int i = 2; i < MAX; i += 2) sp[i] = 2; //even numbers have
    smallest prime factor 2
    for (lli i = 3; i < MAX; i += 2){
        if (!v[i]){
            sp[i] = i;
            for (lli j = i; (j*i) < MAX; j += 2){
                if (!v[j*i]) v[j*i] = true, sp[j*i] = i;
            }
        }
    }
}

int main(){
    Sieve();
    for (int i = 0; i < 50; i++) cout << sp[i] << endl;

    return 0;
}
```

Now, notice the difference between the usual prime factorization and this one! The only problem is, you can't use this for  $n$  large enough in int range. Still, it seems nice to me and pleased me when I first found this.

It's better to precalculate not only smallest prime number, but also quotient  $cp[i] = i / lp[i]$ , to do not unnecessary and TOO SLOW operations of division, especially in case of big number of queries.[→ Reply](#)

kien\_coi\_1997

I think that it is not important. Original source is easy to read and easy to understand. Also, you have to perform divide operations  $\log(n)$  times only. It seems not too big.[→ Reply](#)

Dude, your tricks is really cool but I think there is some problem in your sample code. **Your Sieve() function doesn't store the smallest prime factors properly.** For 45, the smallest prime factor should be 3 where according to your sample code it stores 5![→ Reply](#)

riningan

that's because I forgot to check first if a number already has a smallest prime divisor. Now it is correct. Thanks for pointing the mistake out.

Whats Wrong With this logic every time exception was occurring or it is Same as ABove logic but not Working for java

```
static void Sieve() {
    for (int i = 2; i < MAX; i += 2)
        sp[i] = 2; // even numbers have smallest
        prime factor 2
    for (int i = 3; i < MAX; i += 2) {
        if (!v[i]) {
            sp[i] = i;
            for (int j = i; (j * i) < MAX; j += 2) {
                if (!v[j * i])
                    v[j * i] = true;
```

mshibli786

```

        v[j * i] = true,
        sp[j * i] = i;
    }
}
}
}

```

→ [Reply](#)

I am not able to understand that why is it  $\log(n)$  ???→ [Reply](#)

3 months ago, # ^ | ▲ +6 ▼

Consider the prime factorization  $n = p_1 * p_2 * \dots * p_k$ , where  $p_1, p_2, \dots, p_k$  are the prime factors.  $n$  has at most  $k = \log(n)$  prime factors.

Flatfoot

To understand this think of how you can maximize the number of prime factors. You'll get the most number of prime factors for  $p_1 = p_2 = \dots = p_k = 2$ . So we have  $n = 2^k$ . Solving for  $k$  yields  $k = \log(n)$ .
